COMPLETE INTERSECTIONS PRIMITIVE STRUCTURES ON SPACE CURVES.

PH. ELLIA

Abstract. A multiple structure X on a smooth curve $C \subset \mathbb{P}^3$ is said to be *primitive* if X is locally contained in a smooth surface. We give some numerical conditions for a curve C to be a primitive set theoretical complete intersection (i.e. to have a primitive structure which is a complete intersection).

Introduction.

It is a long standing problem to know whether or not every smooth, irreducible curve $C \subset \mathbb{P}^3$ ($\mathbb{P}^3 = \mathbb{P}^3_k$, k algebraically closed, of characteristic zero) is a set theoretic complete intersection (s.t.c.i.) of two surfaces F_a, F_b. We recall that C is a s.t.c.i. of F_a, F_b if $F_a \cap F_b = C$ as sets, i.e. $\sqrt{(F_a, F_b)} = \mathbb{I}(C)$, where $\mathbb{I}(C) = H^0_*(\mathcal{I}_C)$. It turns out that this is equivalent to the existence of a *multiple structure* X on C which is the complete intersection of F_a and F_b. A multiple structure on C is a locally Cohen-Macaulay curve whose support is C and such that $\deg(X) = md$, where $d = \deg(C)$. The integer m is called the *multiplicity* of X.

Following [1] we can distinguish three cases:

a) X is a *primitive* structure: X is locally contained in a smooth surface; in our case this means that at each point $x \in C$ one of the two surfaces F_a, F_b is smooth.

b) X is a *quasi-primitive* structure: X is generically contained in a smooth surface; in our case this means that there exists a finite subset $T \subset C$ such that for $x \in C \setminus T$, one of the two surfaces F_a, F_b is smooth at x; if $y \in T$, both surfaces are singular at y.

c) X is a *thick* structure: X contains the first infinitesimal neighbourhood of C; in our case this means that both surfaces F_a, F_b are singular along C.

Definition 1. *We say that C is a primitive s.t.c.i. of type (a, b), multiplicity m, if there exists a primitive structure of multiplicity m on C which is the complete intersection of two surfaces of degrees a, b.*

In this note we will consider only primitive s.t.c.i. First we show (Proposition 3) that given any curve C of degree d, genus g, there are only finitely many possible

Key words and phrases. Space curves, multiple structures, set theoretical complete intersections.

(a,b,m) for C to be a primitive s.t.c.i. Now assume X is a primitive multiple structure on C which is a complete intersection: $X = F_a \cap F_b$, $a \leq b$. If $a < b$, F_a is uniquely defined, but F_b moves. For instance X is cut-off schematically by the surfaces of degree b. In particular the general $G \in H^0(\mathcal{I}_X(b))$ is smooth outside of C. We want to use this freedom to control the singularities of G along C. The main result of this note (Theorem 12) states that there exist integers n, k such that for every $p \in Sing(G)$, $(G,C)_p$ is a singularity of type A_n^k (see Definition.8). With this result we are able to give (Theorem 15) some new numerical conditions for C to be a primitive s.t.c.i. When applied to the case where C is a smooth rational quartic curve, these conditions yield (Corollary 16) a slight improvement on a earlier result of Jaffe ([3]). Finally, and unfortunately, we show (Remark 18) that the results of this note are not sufficient for giving a single example of a curve which is not a primitive s.t.c.i. Something else is needed.

As the reader will see, this note owes a lot to Jaffe's work ([3], [4]), so thank you to him. I also thank Massimiliano Mella for pointing to me the paper [5].

1. Primitive structures.

Let $C \subset \mathbb{P}^3$ be a smooth, irreducible curve of degree d, genus g. Assume there is a primitive structure X, of multiplicity m, on C which is the complete intersection of two surfaces F_a, F_b. Let $a = \deg(F_a), b = \deg(F_b)$, $a \leq b$.

The Cohen-Macaulay filtration $C = X_0 \subset X_1 \subset ... \subset X_k = X$ is defined by $X_i = C^{(i)} \cap X$ where $C^{(i)}$ is the i-th infinitesimal neighbourhood of C ($\mathcal{I}_{C^{(i)}} = \mathcal{I}_C^{i+1}$). If X is *primitive*, X_i is locally CM, in fact even locally complete intersection of multiplicity $i+1$ (locally given by (x, y^{i+1}) in suitable coordinates). In particular X_1 is a double structure corresponding to a quotient, L^*, of the conormal bundle N_C^*, and we will say that X is a primitive structure of type L. For $1 \leq i \leq m-1$, we have exact sequences:

$$0 \to L^{*\otimes i} \to \mathcal{O}_{X_i} \to \mathcal{O}_{X_{i-1}} \to 0$$

It follows that:

$$p_a(X) = g - \sum_{i=1}^{m-1} \chi(L^{*\otimes i}) \tag{1}$$

hence:

$$p_a(X) = m(g-1) + 1 + lm(m-1)/2 \tag{2}$$

where $l = \deg(L)$, $L \subset N_C$.

Of course, since $X = F_a \cap F_b$, we also have:

$$p_a(X) = 1 + \frac{ab(a+b-4)}{2} \tag{3}$$

and:

$$dm = ab \tag{4}$$

Combining everything we get:

$$2g - 2 + l(m-1) = d(a+b-4) \tag{5}$$

We recall the following:

Lemma 2. *Let $C \subset \mathbb{P}^3$ be a smooth, irreducible curve of degree d, genus g. Assume C is not contained in a plane. If $L \subset N_C$, then:*

$$l = \deg(L) \leq 3d + 2g - 4 \tag{6}$$

Proof. The line bundle $L(-1) \subset N_C(-1)$ comes from a rank two sub-bundle $E_L \subset T_{\mathbb{P}^3}(-1)|C$ containing $T_C(-1)$. The bundle E_L gives a Gauss map $\varphi_L : C \to \mathbb{P}_3^*$. If $D = \varphi_L(C)$, then D is a curve of degree ≥ 2. We have $\deg(\varphi_L).\deg(D) = 3d + 2g - 2 - l$ (see [2]). The conclusion follows. □

Proposition 3. *Let $C \subset \mathbb{P}^3$ be a smooth, irreducible curve of degree d, genus g. There exist finitely many (l, m, a, b) satisfying (5). In other words there exist finitely many possible (a, b, m) for C to be a primitive s.t.c.i. of surfaces of degrees a, b, with multiplicity m.*

Proof. If $l \leq 0$, from (5) we get $a + b - 4 \leq (2g-2)/d$. Hence we have finitely many (a, b). Since $m = ab/d$, each (a, b) determines m and l. From now on let us assume $l > 0$ and $a \leq b$. By Lemma 2, we have finitely many possible values of l. We may rewrite (5) as follows:

$$a = \alpha(1 + \frac{a}{b} - \frac{4}{b}) + \frac{\gamma}{b} \tag{7}$$

where $\alpha = d^2/l$, $\gamma = 2d(1-g)/l + d$. Clearly $\gamma \leq 3d$. Hence $\gamma/b \leq d\frac{3}{b} \leq d$ (we may assume $b \geq 3$). Now since $a \leq b$, $1 + a/b - 4/b < 2$. It follows that $a < 2\alpha + d = 2d^2/l + d$. So for each value of l we have finitely many possible a. We conclude since to any fixed (a, l) there corresponds a unique b. □

The first candidate for a non s.t.c.i. curve in $\mathbb{P}^3$ is a rational quartic curve. In this case we have:

Lemma 4. *let $C \subset \mathbb{P}^3$ be a smooth rational quartic curve. If C is a primitive s.t.c.i. of type (a, b, m, l) then (a, b, m, l) is one of the following fifteen cases:*

l	7	6	6	5	3	2	2	2
(a,b)	(3,4)	(3,8)	(4,4)	(4,7)	(6,26)	(13,16)	(12,18)	(10,28)
m	3	6	4	7	39	52	54	70

l	2	1	1	1	1	1	1
(a,b)	(9,48)	(28,33)	(22,50)	(20,67)	(19,84)	(18,118)	(17,220)
m	108	231	275	335	399	531	935

Proof. A sub-bundle of $N_C \simeq 2\mathcal{O}_{\mathbb{P}^1}(7)$ has degree at most 7. From (5 we get $l > 0$, so $1 \leq l \leq 7$. Equation (5) reads like: $lm = 4(a+b) - 14 + l$. Since $m = ab/4$, we get: $b(la - 16) = 16a - 56 + 4l$, hence $la = 16 + 16a/b - (56 - 4l)/b$. Since $a \leq b$, we get: $a < 32/l$. Now for each l, $1 \leq l \leq 7$ and for each a, $3 \leq a < 32/l$, we compute $b = (16a - 56 + 4l)/(la - 16)$ (n.b. the case $la - 16 = 0$ is impossible). This can be done by hand but it is faster with a computer. □

Remark 5. *Proposition 3 and Lemma 4 were first proved by Jaffe in* [3] *by a different method.*

2. Singularities and normal bundle.

Let $C \subset S \subset \mathbb{P}^3$ be a smooth curve on the surface S of degree s. Assume $dim(C \cap Sing(S)) = 0$. The inclusion $C \subset S$ yields $\mathcal{O}(-s) \to \mathcal{I}_C$, which, by restriction to C, gives $\sigma : \mathcal{O}_C \to N_C^*(s)$. The section σ vanishes on $C \cap Sing(S)$. More precisely we have an exact sequence:

$$0 \to \mathcal{O}_C(-s) \to N_C^* \to L^* \oplus T \to 0$$

where L is locally free of rank one and where T is a torsion sheaf with support on $C \cap Sing(S)$. This exact sequence defines a surjection $N_C^* \to L^* \to 0$ which in turn defines a double structure on C; this double structure is nothing else than C "doubled on S" (i.e. the greatest locally Cohen-Macaulay subscheme of $C^{(1)} \cap S$ or, equivalently the subscheme of S defined by $\mathcal{I}^{(2)}$ (symbolic power) where $\mathcal{I}$ is the ideal of C in S).

From the exact sequence above we get: $deg(T) = deg(L) - (2g - 2 + d(4 - s))$. Notice that: $deg(T) = deg(L) - deg(\omega_C(4 - s))$ and that if S were smooth we would have $N_{C,S} \simeq \omega_C(4 - s)$; in this sense we can think to L as the "normal bundle" of C in S, with respect with the smooth case, $\deg(L)$ gets a contribution from the singularities of S lying on C.

Definition 6. *In the above situation we define $n(S, C)$, the contribution of the singularities of S to the normal bundle of C, by: $n(S, C) := deg(L) + d(s-4) - 2g + 2$.*

Remark 7. *In the terminology of* [3], *$n(S, C) = p_1(S, C)$. Of course, the computation of $n(S, C)$ is a local problem: $n(S, C) = \sum_{p \in Sing(S) \cap C} n(S, C)_p$.*

Definition 8. *Following* [3], *a surface-curve pair (S, C) is a surface S with a curve $C \subset S$ such that C is a regular scheme not contained in $Sing(S)$. Given a surface-curve pair, one may consider, for every p in C the* local pair *$(S, C)_p$; this amounts to give the data (A, I) where $A = \mathcal{O}_{S,p}$ and where $I \subset A$ is the ideal of C. Assume p is a singularity of type A_n. Let $E_1, ..., E_n$ (with the natural numbering) denote the exceptional curves over p in the minimal resolution $f : S' \to S$. Then $\overline{C}$,*

the strict transform of C, meets a unique exceptional curve E_k and $\overline{C}.E_k = 1$. In this case we will say that $(S,C)_p$ is a singularity of type A_n^k.

If p is an A_n singularity, every $(S,C)_p$ is analytically isomorphic to some A_n^k for some $k \leq \frac{n+1}{2}$ ([4]).

Lemma 9. *Assume $(S,C)_p$ is an A_n^k singularity, then $\overline{C}.E = \dfrac{k(n+1-k)}{(n+1)}$.*

Proof. We have $f^*(C) = \overline{C} + \sum_{i=1}^n f_i E_i$ ($E = \sum_{i=1}^n f_i E_i$), writing $f^*(C).E_j = 0 = \delta_{jk} + \sum_{i=1}^n f_i E_i E_j$, for $1 \leq j \leq n$, we get a linear system in the f_i's; solving this system, we get $f_k = \frac{k(n+1-k)}{(n+1)}$. See [3] Prop.5.8 for more details. □

Lemma 10. *If $(S,C)_p$ is an A_n^k singularity with $k \leq \frac{n+1}{2}$, then $n(S,C)_p = k$.*

Proof. Since the question is local we may assume S given by $xy + yz^k + xz^{n-k+1} = 0$ and C given by $I = (x,y)$ (cf [3]). Looking at the equation of S mod.I^2, we get $n(S,C)_p = min\{k, n-k+1\} = k$ under our assumption. □

We will need also the following

Lemma 11. *Let $C \subset F_b$. Assume that F_b is normal with only* rational double points *(A, D, E double points). Let $f : \overline{F} \to F$ be the minimal resolution and let $f^*C = \overline{C} + E$ where $\overline{C}$ is the strict transform of C and where E is an effective $\mathbb{Q}$ divisor supported on the exceptional locus. With notations as above, if C is a set theoretic complete intersection on F_b, then $\overline{C}.E = d(b-4) + \dfrac{d^2}{b} + 2 - 2g$.*

Proof. Since F_b has only rational singularities, $\omega_{\overline{F}} = f^*(\omega_{F_b}) \simeq f^*(\mathcal{O}_{F_b}(b-4))$. It follows that $\overline{C}.\overline{K} = d(b-4)$. By adjunction: $\overline{C}^2 + \overline{CK} = 2g-2$ and we get $\overline{C}^2 = 2g - 2 - d(b-4)$. If C is a set theoretic complete intersection on F_b, then $f^*(mC) = f^*(\mathcal{O}_{F_b}(a))$. It follows that $f^*(C) = \dfrac{a}{(b-4)m}\overline{K}$, as $\mathbb{Q}$-divisor. Now, on the one hand: $f^*(C).\overline{C} = (\overline{C}+E)\overline{C} = 2g - 2 - d(b-4) + \overline{C}.E$ and on the other hand $f^*(C).\overline{C} = \dfrac{a}{(b-4)m}\overline{C}.\overline{K} = \dfrac{d^2}{b}$ (using $md = ab$). Combining the two we get the result. □

3. A uniformity result.

Assume X is a primitive multiple structure on C which is a complete intersection: $X = F_a \cap F_b$, $a \leq b$. If $a < b$, F_a is uniquely defined, but F_b moves: we may replace it by $F_a P + \lambda F_b$. For instance X is cut-off schematically by the surfaces of degree b. In particular the general $G \in H^0(\mathcal{I}_X(b))$ is smooth outside of C. We want to

use this freedom to control the singularities of G along C, where $G \in H^0(\mathcal{I}_X(b))$ is general. We have:

Theorem 12. *Let $C \subset \mathbb{P}^3$ be a smooth, irreducible curve. Assume there exists a primitive structure, X, on C such that $X = F_a \cap F_b$, with $a \leq b$. Then the general surface, G, of degree b containing X is normal with at most rational singularities along C. More precisely, G is smooth outside of C and there exist integers n, k such that for every $p \in Sing(G)$, $(G, C)_p$ is a singularity of type A_n^k.*

Proof. Since $\mathcal{I}_X(b)$ is generated by global sections, by Bertini's theorem, the general surface of degree b containing X is smooth outside of C, so we may assume that F_b is smooth out of C. Consider a general pencil, Δ, of degree b surfaces containing X: $\lambda F_a.P + \mu F_b$. As already observed, the general surface of this pencil is smooth outside of C. Moreover, since X is primitive, for every $x \in C$ there exists a surface of the pencil which is smooth at x, by [5] this implies that the general surface, S, of the pencil has at most singularities of type A_n. Indeed by [5] Theorem 4.4 S has only cA singularities. But normal cA singularities are canonical and since we are dealing with normal singularities of surfaces, they are rational (see Theorem 3.6 of [5]). Finally since the quadratic part of a local equation has rank at least 2, they are of type A_n.

The pencil $\Delta \simeq \mathbb{P}^1$ gives a family $\mathcal{F} \subset \mathbb{P}^3_\Delta \to \Delta$ of degree b surfaces with only rational singularities. We may consider (after a base-change if necessary) a simultaneous resolution of the singularities, this resolution is obtained by successive blow-ups ([7]). After a certain number of blow-up, the general fiber of $\mathcal{F} \to \Delta$ is smooth; this shows that there exists n such that the general member of Δ has only A_n singularities.

We have a morphism $g : C \to \Delta : x \to F_x$ where F_x is the unique surface of Δ which is singular at x. Let $Y \subset C \times \Delta$ be the graph of g. Then Y is a unisecant on the ruled surface $p : C \times \mathbb{P}^1 \to C$, (we have identified Δ to $\mathbb{P}^1$) hence Y is smooth, irreducible. In $\mathbb{P}^3 \times \mathbb{P}^1$ consider the incidence $\mathcal{S} = \{(x, t) \mid x \in F_t\}$. The inclusion $\mathcal{C} = C \times \mathbb{P}^1 \subset \mathcal{S}$ gives a morphism $\mathcal{I}_\mathcal{S} \to \mathcal{I}_\mathcal{C}$. Restricting to $\mathcal{C}$, we get: $\varphi : p^*(\mathcal{O}(-b)) \otimes q^*(\mathcal{O}(-1)) \to p*(N_C^*)$, when restricted to a fiber of $q : C \times \mathbb{P}^1 \to \mathbb{P}^1$, this morphism is the morphism $\mathcal{O}(-b) \to N_C^*$ induced by F_t. The cokernel of φ has a torsion subsheaf, $\mathcal{T}$, supported on Y. Since $\mathcal{T}$ is locally free on an open subset of Y, we conclude (using Lemma 10) that there exists k such that the general member of Δ has at most A_n^k-singularities along C. □

A first consequence:

Lemma 13. *Let X be a primitive structure of type L on a smooth, irreducible curve C, of degree d, genus g. Assume $X = F_a \cap F_b$, $a \leq b$. Assume F_b is general in the sense of Theorem 12, i.e. there exist n, k such that F_b has α singularities of type A_n^k on C and is smooth outside of C. Then $\alpha k = d(b-4) - 2g + 2 + l$.*

Proof. We have $n(F_b, C) = \deg(L) - \deg \omega_C(4-b) = l - 2g + 2 + d(b-4)$ and the conclusion follows from Lemma 10. □

We have other numerical conditions:

Proposition 14. *Assume X is a multiplicity m primitive structure of type L on a smooth, irreducible curve C such that $X = F_a \cap F_b$ with $a \leq b$, $b > 4$. Then there exist positive integers α, n, k with $k \leq \frac{n+1}{2}$ satisfying the following conditions:*

(1) $\alpha k = d(b-4) - 2g + 2 + l$
(2) $n + 1 = \dfrac{\alpha b k^2}{lb - d^2}$
(3) $\alpha n < \dfrac{\alpha n(n+2)}{n+1} \leq \dfrac{2b(b-1)^2}{3}$
(4) *In particular:* $\dfrac{(A+l)(bA+d^2)}{lb-d^2} < \dfrac{2b(b-1)^2}{3}$, *where:* $A := d(b-4) - 2g + 2$.

Proof. We may assume that F_b is general in the sense of Theorem 12, hence there exist n, k such that F_b is normal and has α singularities of type A_n^k on C; this defines the numbers α, n, k.

Condition (1) is Lemma 13.

By Lemma 11, $\overline{C}.E = A + (d^2/b)$ ($A := d(b-4) - 2g + 2$). Under our assumption and using Lemma 9 we get $\overline{C}.E = \frac{\alpha k(n+1-k)}{n+1}$. It follows that $A + (d^2/b) = \frac{\alpha k(n+1-k)}{n+1}$ (*). The difference (1)-(*) yields $(\alpha k^2)/(n+1) = (bl - d^2)/b$ and (2) follows.

From Miyaoka's inequality ([6] Cor.1.3 with $D = 0$) we get $\sum_{p \in Sing(F_b)} \nu(p) \leq c_2(\tilde{F}_b) - \frac{c_1^2(\tilde{F}_b)}{3}$. For an A_n singularity, $\nu = (n + 1 - \frac{1}{n+1})$ (the Euler number is $n+1$ and $\mid G \mid = n+1$). Since $c_1^2(\tilde{F}_b) = b(b-4)^2$ and since $c_2(\tilde{F}_b) = b^3 - 4b^2 + 6b$, we get $\frac{\alpha n(n+2)}{n+1} \leq \frac{2b(b-1)^2}{3}$ and (3) follows.

From (2) $n + 1 = (\alpha b k^2)/(lb - d^2)$. From (1) $\alpha k = A + l$. It follows that $n = \frac{bk(A+l)}{lb-d^2} - 1$. Hence $\alpha n = \frac{\alpha bk(A+l)}{lb-d^2} - \alpha$. From (1), $\alpha \leq A + l$. This implies $\alpha n \geq \frac{\alpha bk(A+l)}{lb-d^2} - (A+l) = (A+l)[b(\alpha k - l) + d^2]/(lb - d^2) = (A+l)[bA + d^2]/(lb - d^2)$. We conclude with (3). □

Gathering everything together:

Theorem 15. *Let $C \subset \mathbb{P}^3$ be a smooth, irreducible curve of degree d, genus g. If C is a primitive set theoretic complete intersection, then there exist integers a, b, l, m, α, n, k such that:*

(1) $md = ab$
(2) $2g - 2 + l(m-1) = d(a+b-4)$
(3) $\alpha k = A + l$, *where* $A := d(b-4) - 2g + 2$
(4) $\alpha n < 2b(b-1)^2/3$
(5) $3(A+l)(bA+d^2) < 2b(lb-d^2)(b-1)^2$

Applying this to the case $d = 4, g = 0$ we get:

Corollary 16. *Let $C \subset \mathbb{P}^3$ be a smooth rational quartic curve. If C is a primitive s.t.c.i. of type (a, b, m, l), then (a, b, m, l) is one of the following ten cases:* $(a, b, l) \in \{(4, 7, 5), (6, 26, 3), (12, 18, 2), (10, 28, 2), (9, 48, 2), (22, 50, 1), (20, 67, 1), (19, 84, 1), (18, 118, 1), (17, 220, 1)\}$.

Proof. We take the list of Lemma 4 and we apply Theorem 15. Thanks to condition (5) we can exclude five cases: $(a, b) = (3, 4), (3, 8), (4, 4), (13, 16), (28, 33)$. □

Remark 17. *The cases with $a = 3$ were already excluded in* [3] *in a different way, so our improvement is limited to the exclusion of three cases ($(4, 4), (13, 16), (28, 33)$).*

Remark 18. *Although for given (d, g) we know that there is a finite number of possible (a, b, m, l) (see Proposition 3) it turns out that for every (d, g), the numerical conditions of Theorem 15 are always fulfilled. Indeed let us set $l = 1$. From (2) we get: $m = d(a + b - 4) - 2g + 3$. Since $m = ab/d$ by (1), it follows that: $b = (d^2a - 4d^2 - 2gd + 3d)/(a - d^2)$. Set $a = d^2 + 1$, then $b = d^4 - 3d^2 + 3d - 2gd$. Since $g \leq (d-2)^2/4$ by Castelnuovo's bound, we have $0 < a \leq b$. Now take $k = 1$, so that $\alpha = A + 1$ by (3). Condition (4) is fulfilled by $n = 1$ (and also by many other values of n since $2b(b-1)^2/(A+1) \sim 2d^7/3$). Finally to check (5) first observe that under our assumptions: $A + 1 \leq db$ so it is enough to show that:*

$$0 < 2b^3 - b^2(4 + 5d^2) + 2b(1 + 4d^2) - 2d^2 - 3d^3$$

Now since $b \geq d^4 - d^3$ we have $2b(1 + 4d^2) - 2d2 - 3d^3 > 0$ and $2b^3 - b^2(4 + 5d^2) > 0$.
